(*1. Department of Physics, East China Normal University, Shanghai 200241, China*)

Abstract: The recent progresses on the wobbling motion are briefly introduced. So far 17 wobbling candidates have been reported in odd- A and even-even nuclei that spread over $A \approx 100, 130, 160$, and 190 mass regions. The two-quasiparticle configuration wobbling in ^{130}Ba and the wobbling motion in a triaxial rotor are taken as examples in this paper to show the wobbling motion in even-even nuclei. The combination of covariant density functional theory and particle rotor model (CDFT+PRM) is a powerful theoretical method to study the wobbling motion. The time evolution of the wobbling motion is an interesting topic, from which the wobbling nature is intuitively revealed.

Key words: Wobbling motion; Even-even nucleus; Two-quasiparticle; Time evolution

CLC number: O571.2 **Document code:** A **DOI:** [10.11804/NuclPhysRev.00.01.00](https://doi.org/10.11804/NuclPhysRev.00.01.00)

1 Recent progresses

The nuclear wobbling mode, which is uniquely related to triaxiality of nuclear shape, has become an hot topic in recent years from both experimental and theoretical sides. It was first proposed by Bohr and Mottelson^[1] for a triaxial rotor, i.e., for an even-even nuclei without coupling quasiparticles and the only angular momentum in the system is the total angular momentum. The nucleus rotates around the principal axis having the largest moment of inertia, usually the intermediate axis, which executes harmonic oscillations about the space-fixed angular momentum vector. The expected energy spectra related to this motion are characterized by a series of rotational $E2$ bands corresponding to the different oscillation quanta (n). The transitions among them are $\Delta I = 1$ transitions with dominant $E2$ character, since the wobbling is generated by the motion of the entire triaxial charge density with respect to the angular momentum vector.

Although Bohr and Mottelson predicted this motion for even-even nuclei where no intrinsic angular momentum is involved, the phenomenon in this simple form has not been

experimentally confirmed yet. In contrast, the possible presence of the angular momentum coming from the intrinsic single particle motion can in many ways make the nuclear wobbling mode much richer in its structure and easier to be observed, e.g., in the odd- A mass nuclei. When the triaxial rotor is coupled to a high- j valence particle, Frauendorf and Dönau proposed that there are two kinds of wobbling modes, namely, longitudinal wobbling (LW) and transverse wobbling (TW)^[2]. The longitudinal wobbling refers to that the angular momentum of the high- j valence particles is parallel to the principal axis with the largest moment of inertia, while the transverse wobble the angular momentum of the high- j valence particles perpendicular to the principal axis with the largest moment of inertia. Very recently, Chen and Frauendorf further proposed a more comprehensive classification for the wobbling motion based on the topology of the classical orbits visualized by the corresponding spin coherent state (SCS) maps^[3]: LW corresponds to a revolution of total angular momentum \mathbf{J} around the axis with the largest moment of inertia and TW corresponds to a revolution of \mathbf{J} around an axis perpendicular to the axis with the largest moment of inertia. The salient experimental criteria for TW and LW are manifested on the excitation energy and the $E2$ transition. The excitation energy of the LW (TW) states increases (decreases) with increasing angular momentum. Both TW and LW have enhanced $I \rightarrow I - 1$ $E2$ transitions between adjacent wobbling bands.

The reported wobbling candidates in the nuclear chart

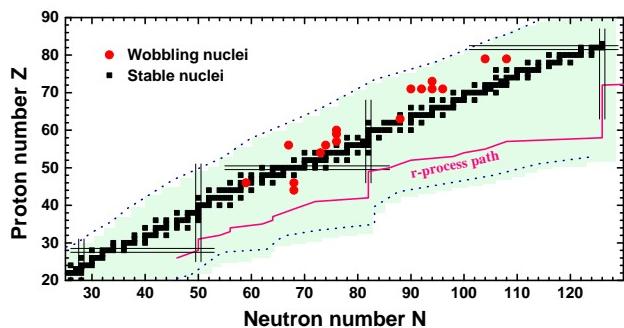

Fig. 1 (Color online) Reported wobbling candidates are spread over the $A \approx 100, 130, 160$, and 190 mass regions.

up to now are summarized in Fig. 1. Most of them are in odd-proton nuclei, including ^{161}Lu ^[4], ^{163}Lu ^[5-6], ^{165}Lu ^[7], ^{167}Lu ^[8], ^{167}Ta ^[9], and ^{151}Eu ^[10] in $A \approx 160$ mass region, ^{135}Pr ^[11-12], ^{133}La ^[13], ^{130}Ba ^[14-15], ^{127}Xe ^[16], ^{133}Ba ^[17], and ^{136}Nd ^[18] in the $A \approx 130$ mass region. Of which the ^{135}Pr is the first observation of transverse wobbling at low deformation^[11-12] and the ^{130}Ba is the first example of two-quasiparticle wobbling bands in an even-even nucleus^[14-15,19]. In the heavier $A \approx 190$ mass region, the candidates are ^{187}Au ^[20] and ^{183}Au ^[21]. In the lighter $A \approx 100$ mass region, there is only one candidate ^{105}Pd with odd neutron number $N = 59$, which had been suggested as TW and the first nucleus that the wobbling excited state is based on a quasi-neutron configuration^[22]. One is aware of that some of these suggested wobblers remain controversial^[23-30].

Theoretically, the triaxial rotor model^[1,31] or particle rotor model (PRM)^[2-3,15,32-36] and its approximation solutions based on the angular momentum coherent states^[37-39], the cranking model plus random phase approximation (RPA)^[40-42], the collective Hamiltonian based on tilted axis cranking model^[43-44], as well as the project shell model^[19,45-46] have been developed to study the wobbling motion. In particular, the combination of quantal PRM and the state-of-art covariant density functional theory (CDFT) (abbreviate as CDFT+PRM)^[47-49] have been used to describe the wobbling candidates reported in the ^{105}Pd ^[22], ^{130}Ba ^[15], ^{187}Au ^[20], and ^{183}Au ^[21]. In this framework, the adiabatic and configuration fixed constraint triaxial CDFT calculations are first carried out to obtain the potential energy surfaces in the β - γ , the potential energy curves along the β direction, as well as the single-particle energy levels to analyze the possible existence of the configuration and deformation parameters. The obtained configuration and deformation parameters are then input to the PRM to calculate the energy

spectra, the electromagnetic transition probabilities, as well as the angular momentum geometries of the wobbling motion. The underlying physics of the observed rotational bands can be eventually revealed.

As mentioned before, the evidence for wobbling in even-even nuclei is fragmentary. In this proceeding we will present some brief results on the wobbling motion in an even-even nucleus. It contains two parts. One is the wobbling motion in a two-quasiparticle configuration, and the other one is the time-evolution of wobbling motion for a triaxial rotor.

2 Two-quasiparticle wobbling

In the following, we take the two-quasiparticle wobbling candidate ^{130}Ba as an example to show the calculations within the CDFT+PRM approach.

As mentioned, the ^{130}Ba is the first example of the two-quasiparticle wobbling bands in an even-even nucleus^[14-15,19]. The calculated energy spectra by the PRM in comparison with the experimental has been given in Ref.^[15]. Here we show the potential energy curve as a function of deformation β in Fig. 2 obtained by the adiabatic and configuration fixed constraint triaxial CDFT calculations. In the calculations, the effective interaction PC-PK1^[50] was used, while the pairing correlations were neglected for simplicity. The Dirac equation was solved employing a spherical harmonic oscillator basis with 12 major shells. The adiabatic constrained CDFT calculation is to solve the Dirac equation by filling the protons and neutrons into the single-particle energy levels according to their energies from the bottom of the well. During the constrained calculations for the given deformation β , the triaxial deformation is automatically obtained by minimizing the energy. The configuration fixed constrained calculation requires that the occupied single-particle orbits are fixed during the constrained calculation with $|\langle\phi_j(\beta + \delta\beta)|\phi_i(\beta)\rangle| \approx 1$ ^[47] (in practical calculations the overlap is set as ≥ 0.90). One sees clearly from Fig. 2 that the advantages of the configuration fixed constrained calculations is that the continuous and smooth energy curves and the unambiguous local minima for each configuration are yielded in comparison with the irregularities of energy curve in adiabatic constrained calculations.

The ground state (labeled as “A” in Fig. 2) deformation of ^{130}Ba is $(\beta, \gamma) = (0.23, 13.9^\circ)$. There are several local minima in the potential energy curve, in which the protons and neutrons are also zero-quasiparticle configuration. To find

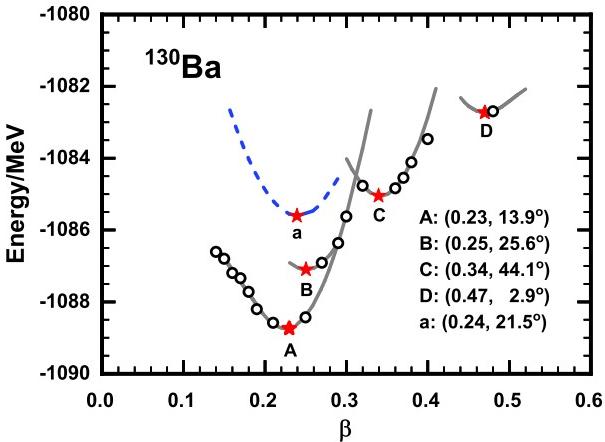

Fig. 2 (Color online) The potential energy as a function of deformation β in adiabatic (open circles) and configuration-fixed (lines) constrained triaxial CDFT calculations with the PC-PK1 effective interaction for ^{130}Ba . The local minima in the energy surfaces for fixed configuration are represented as stars and labeled, respectively, as A-D and a.

the configuration responsible for establishing the wobbling motion in ^{130}Ba , we excited one paired protons to the $h_{11/2}$ orbit and do the configuration fixed calculations to obtain the excited configuration $\pi(1h_{11/2})^2$ (labeled as “a” in Fig. 2). Definitely other excited configurations can be obtained in a similar way. They are used to describe the other observed rotational bands^[14]. The configuration $\pi(1h_{11/2})^2$ has the deformation $(\beta, \gamma) = (0.24, 21.5^\circ)$ and an excitation energy of 3.13 MeV with respect to the ground state, which is comparable with the experimental excitation energy of 3.79 MeV of the $I = 10\hbar$ state of the yrast wobbling band^[14]. The obtained deformation parameters and configuration information are then input to the PRM to describe the experimental energy spectra, energy difference between the two bands, as well as the available electromagnetic transition probabilities $B(M1)_{\text{out}}/B(E2)_{\text{in}}$ and $B(E2)_{\text{out}}/B(E2)_{\text{in}}$ ^[51]. One finds that in comparison with TW in odd- A nuclei, the mixing ratios $\delta = \langle E2 \rangle_{\text{out}}/\langle M1 \rangle_{\text{out}}$ in the ^{130}Ba are in fact small. This is attributed to the fact that one more high- j quasiparticle is involved in the two-quasiparticle configuration, which enlarges the $M1$ matrix elements. This is a characteristic for the two-quasiparticle wobbling motion. The detailed analysis of the angular momentum geometry demonstrates the much more stable TW character of the excited bands in ^{130}Ba than those in odd- A nuclei^[51], since the two-quasiparticle can have much larger alignment along the short axis. The detail results can be found in Ref.^[51].

The success of the CDFT+PRM on the study of the two-

quasiparticle wobbling motion in ^{130}Ba ^[51] has motivated the project shell model to study the wobbling in ^{130}Ba ^[19] and ^{136}Nd ^[46], the collective Hamiltonian constructed from a semiclassical treatment to study the wobbling in ^{130}Ba , ^{134}Ce , $^{136,138}\text{Nd}$ ^[52], as well as the experimental study on the wobbling in ^{136}Nd ^[18]. More candidates of two-quasiparticle wobbling nuclei are expected on this or other mass regions. The related work along this direction is in progress^[53]. It is also worth pointing out that the CDFT+PRM has also been applied successfully on the study of the nuclear chirality^[54-65] and the single particle and collective motion in the light nuclei^[66-67].

3 Time evolution study

The CDFT+PRM provides a microscopic and quantal approach to study the wobbling motion. In the following, a classical view on the wobbling motion is provided by investigating the time evolution of wobbling motion. To study the time evolution of wobbling motion, we start from the triaxial rotor Hamiltonian, which is written as^[1]

$$H_{\text{TR}} = \sum_{i=1,2,3} \frac{\hat{J}_i^2}{2J_i}, \quad (1)$$

where \hat{J}_i are the components of the collective angular momentum with respect to the principal axes of the rotor and J_i the corresponding moments of inertia. Classically, the angular momentum components are expressed, in the spherical coordinate frame for a given spin value I , by the polar angle θ and azimuthal angle ϕ as

$$\begin{aligned} J_1 &= \sqrt{I(I+1)} \sin \theta \cos \phi, \\ J_2 &= \sqrt{I(I+1)} \sin \theta \sin \phi, \\ J_3 &= \sqrt{I(I+1)} \cos \theta. \end{aligned} \quad (2)$$

Here, θ is defined as the angle between \mathbf{J} and the long (l) axis, and ϕ is the angle between the projection of \mathbf{J} onto the short-intermediate (sm) plane and the s -axis.

The orbits of the angular momentum on the unit angular momentum sphere are determined by the implicit equation^[3]

$$E = \frac{J_3^2}{2B(\phi)} + V(\phi), \quad (3)$$

$$V(\phi) = I(I+1) \left(\frac{\sin^2 \phi}{2J_2} + \frac{\cos^2 \phi}{2J_1} \right), \quad (4)$$

$$\frac{1}{2B(\phi)} = \left(\frac{1}{2J_3} - \frac{\sin^2 \phi}{2J_2} - \frac{\cos^2 \phi}{2J_1} \right), \quad (5)$$

which are obtained by the intersection lines between the

sphere of constant angular momentum $\mathbf{J}^2 = J_1^2 + J_2^2 + J_3^2 = I(I+1)$ and the ellipsoid of constant energy given in Eq. (1).

According to the Euler equation for a classical rotor, the angular velocity tangential to the orbit is^[3]

$$\omega_{\parallel}(\phi) = \frac{dI_{\parallel}}{dt} = \sqrt{\left(\frac{d\phi}{dt}\right)^2 + \left(\frac{d\theta}{dt}\right)^2}, \quad (6)$$

$$\frac{d\phi}{dt} = \sqrt{I(I+1)} \cos \theta \left(\frac{\cos^2 \phi}{J_1} + \frac{\sin^2 \phi}{J_2} - \frac{1}{J_3} \right), \quad (7)$$

$$\frac{d\theta}{dt} = \sqrt{I(I+1)} \sin \theta \left(\frac{1}{J_1} - \frac{1}{J_2} \right) \sin \phi \cos \phi, \quad (8)$$

where $\theta(\phi)$ can be derived from the Eq. (3) for a given energy value E_v , i.e.,

$$\cos^2 \theta(\phi) = \frac{2B(\phi)}{I(I+1)} [E_v - V(\phi)]. \quad (9)$$

Therefore, once the moment of inertia and the initial condition of the triaxial rotor are known, the time evolution equation Eqs. (7)-(8) can be solved.

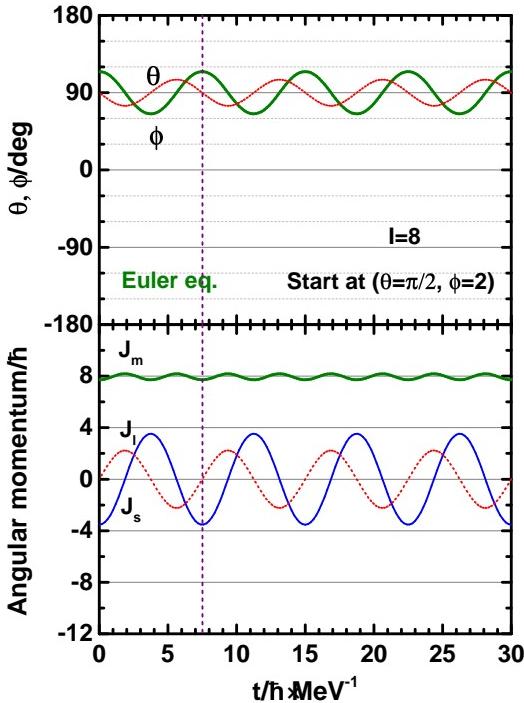

Fig. 3 (Color online) Upper panel: The orientation angles θ and ϕ as a function of time t at $I = 8\hbar$ obtained by solving the Euler equation Eq. (6). Lower panel: The corresponding angular momentum components along the intermediate (J_m), short (J_s), and long (J_l) principal axis of the triaxial rotor as a function of t .

In Fig. 3, an example of the orientation angles θ and ϕ as well as the corresponding angular momentum components along the intermediate (J_m), short (J_s), and long (J_l)

principal axis of the triaxial rotor are shown as functions of t for given values of $I = 8\hbar$ and $J_m = 30 \hbar^2/\text{MeV}$, $J_s = 10 \hbar^2/\text{MeV}$, and $J_l = 5 \hbar^2/\text{MeV}$. This system has been studied in the framework of triaxial rotor model^[3] and has been revealed as a good example to show the wobbling picture. The initial condition is chosen as $(\theta = \pi/2, \phi = 2)$, which corresponds to the lowest energy state orbit calculated by (9) with $E_1 = 1.616 \text{ MeV}$. The θ and ϕ oscillate with respect to $\theta = \pi/2$ and $\phi = \pi/2$, respectively. Correspondingly, the angular momentum aligns mainly along the m -axis with $J_m \approx 8\hbar$. The J_s and J_l are small but not negligible. They drive the rotational axis precess and wobble around the axis with the largest moment of inertia. All of these characteristics present the wobbling motion with respect to the m -axis.

Both θ and ϕ develop periodically with time with the same period of $T = 7.5 \hbar/\text{MeV}$. The periodic characters are also seen for the angular momentum components. The period T will vary as the initial condition of (θ, ϕ) or say the excitation energy E . With a bit higher E , the T increases. In particular, T will become infinite when the initial condition is chosen as $(\theta = \pi/2, \phi = 0)$, i.e., starting from the s -axis. Namely, the wobbling motion with respect to the s -axis (intermediate moment of inertia axis) does not exist. It is worth pointing out that the time evolution picture will still maintain as spin increases. The corresponding wobbling amplitudes will become reduced gradually. More detailed results will be published elsewhere^[68].

4 Summary

In summary, the recent progresses on the wobbling motion are briefly introduced. So far 17 wobbling candidates have been reported in odd- A and even-even nuclei that spread over $A \approx 100, 130, 160$, and 190 mass regions. Various kinds of theoretical approach have been developed to study the wobbling motion. Of which the CDFT+PRM is a powerful tool to study the wobbling motion. From the CDFT calculations, the possible existence of the configuration and deformation parameters can be obtained in a microscopic manner. From the PRM calculations, the experimental spectroscopic properties can be well described and the underlying physics can be explored in a fully quantal view. The two-quasiparticle configuration wobbling in ^{130}Ba and the wobbling motion in a triaxial rotor are taken as examples to show the wobbling motion in even-even nuclei. The time evolution

of the wobbling motion is an interesting topic, from which the wobbling nature is intuitively revealed. Further experimental and theoretical efforts on the wobbling motion are expected.

CNPC2023: 偶偶原子核中的摇摆运动

孙博文¹, 纪琪芝¹, 陈启博¹

(1. 华东师范大学物理与电子科学学院, 上海 200241)

摘要: 本文简要介绍了摇摆运动的近期研究进展。目前, 在质量数为 100、130、160、190 核区的奇 A 核与偶偶核中已报导了 17 个摇摆候选核。本文以 ^{130}Ba 中的两准粒子组态摇摆及三轴转子的摇摆运动为例说明偶偶核中的摇摆运动。基于协变密度泛函理论与粒子转子模型 (CDFT+PRM) 是研究摇摆运动强有力的方法。摇摆运动的含时演化问题能够直观地揭示摇摆的本质, 值得深入探究。

关键词: 摆摆运动; 偶偶核; 两准粒子; 含时演化
